## INTRODUCTION

The main objective of this study was to evaluate the load transfer efficiency for longitudinal joints with and without keyways. In order to satisfy that objective, test sections were built as part of a newly constructed concrete pavement on SR 9A in Jacksonville, Florida. The pavement cross section consisted of 318 mm (12.5 inches) of concrete on top of 152 mm (6 inches) of granular base materials. The embankment/ subgrade thickness was 1219 mm (48 inches). The test sections had two lanes and shoulders. The distance between the joints tested and the free edge was 22 feet. Figure 1 shows typical keyway and non-keyway joints. Keyway and non-keyway joints had number 4 tie bars with a spacing of about 14 inches in compliance with the FDOT Jointed Plain Concrete Pavement Design Manual. The slip form paver used to construct the pavement had a mechanical device to insert tie bars automatically. It should be emphasized that the test results in this report represent joint performance of newly constructed roadway prior to the application of any traffic. The joints performance may change due to the repeated traffic applications in the future.

## DATA COLLECTION

After finishing the construction of the experimental sections and prior to opening the pavement to regular traffic, deflection measurements were collected on 20 slabs with Keyway joints and 20 slabs without Keyway joints. All deflection measurements were performed with the Florida Department of Transportation (FDOT) Falling Weight Deflectometer (FWD). The standard 550 Kpa which corresponds to the standard axle load was used in all FWD testing. Testing was done at two locations of every test slab. As shown in Figure 2, one of the testing location was near the centers of the slabs while the other was near the corners of the slabs. The

deflection testing was performed twice at all locations. Once in the early morning (a.m.) and a second time late in the afternoon (p.m.). The difference in temperature between the two testing times was 30E F. The above testing combinations resulted in eight data sets as shown in Table 1.

## DATA ANALYSIS

After collecting all the necessary data, the deflection measurements were normalized to reflect the standard load of 565 Kpa. The analysis was then performed in three steps. The first step consisted of calculating the load transfer efficiency across the longitudinal joints at each test location. The following simple equation was utilized in these calculations:

$$E = (P_5 / P_1) * 100 \dots \dots \dots (1)$$

Where:

E: The efficiency of load transfer across the joint.  
 P5: Deflection from sensor # 5 (see Figure 1).  
 P1: Deflection from sensor # 1 (see Figure 1).

The second step in the analysis consisted of plotting the deflections for keyway versus non-keyway joints. Statistical analysis was then performed in the final step of the analysis. The following sections describe these steps in detail.

## LOAD TRANSFER EFFICIENCY

Equation 1 was utilized in calculating the load transfer efficiencies at all locations. Table 2 shows the standard deviation, average, highest, and lowest load transfer efficiency values for each data set. It is clear from Table 2 that all data sets had on the average high load transfer efficiencies which is expected for a newly constructed pavement section.

## DEFLECTION PLOTS

The deflection measurements from sensors number 1 and 5 were plotted for various testing conditions to visually compare the deflections from keyway and non-keyway joints. Figures 3 and 4 show how most deflection measurements obtained at mid slabs were lower for the keyway joints. On the other hand, Figures 5 and 6 show no particular trends for the deflections at corner locations.

## STATISTICAL ANALYSIS

The statistical analysis consisted of performing the t-test on the various data sets to determine the effectiveness of keyway joints. The analysis was first performed on the load transfer efficiency of keyway versus non-keyway joints. Similar analysis was later performed on the deflection measurements from sensors 1 and 5. The following sections summarize the findings from this analysis.

### **Effect of Keyways on Load Transfer Efficiency**

The load transfer efficiency of keyway joints were compared to the non-keyway joints statistically. Table 3 shows the results from the t-test including the critical and calculated t values. The calculated t values must be higher than the critical values in order to conclude that the data sets compared are different. It is clear from Table 3 that regardless of testing conditions (time of day or testing location), Keyway and non-keyway joints provided similar load transfer efficiency.

### **Effect of Testing Time on Load Transfer Efficiency**

The t-test was also performed to determine if testing time (a.m. vs p.m.) Would affect load transfer efficiency. The results from the analysis are summarized in Table 4. It is clear from Table 4 that in two out of the four cases, the efficiency of load transfer was affected by the

testing time. In all four cases, the load transfer efficiencies were less when tested in the afternoon. However, only in two cases the differences were significant statistically. The reduction in load transfer efficiency is most likely due to the curling of the slabs.

### **Effect of Testing Location on Load Transfer Efficiency**

Another factor that might influence the load transfer efficiency is the location of testing. The t-test was performed to compare the load transfer efficiency at the two testing locations. Table 5 summarizes those results which indicate that in three out of the four cases, the testing location affected the load transfer efficiency. These load transfer efficiencies are normally higher at mid slabs than at the corners of the slabs.

### **Effect of Keyways on Deflection Measurements**

The final factor that was examined in this study was the effect of Keyways on the deflection measurements from sensors 1 and 5. Table 6 shows the average deflection values for various testing conditions. It is clear from Table 6 that average deflection measurements for keyway joints were less than those for non-keyway joints. The percentages of reduction in deflection were higher than 10 percent for all mid slab testing locations. The t-test was performed on the deflection measurements to determine if the differences were significant statistically. Table 7 summarizes the results from the t-test. Keyway joints resulted in statistically less deflection measurements for all mid slabs testing conditions. Keyways were not as effective in reducing deflections at corner locations.

Although deflection measurements at mid slabs of keyway joints were about 10 to 15 percent less than the deflections at non-keyway joints, these percentages are far less than the fluctuations in deflection measurements due to testing at different time of the day. As shown in

Table 8, the p.m. deflections can be about 40 percent less than the a.m. deflections. Therefore, the relatively smaller 10 to 15 percent reduction in deflection due to keyway joints may not be as effective in increasing the service life of the pavement especially that no real reduction was achieved at the weaker corner locations.

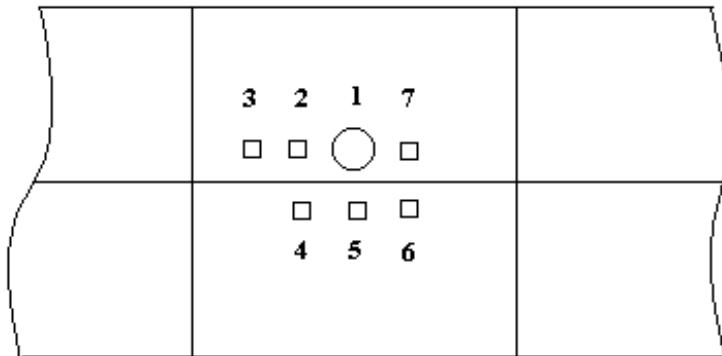

Additional analysis was performed on FWD deflection measurements at the heavier loads of 750 KPa and 900 KPa. Keyways seem to offer more friction at longitudinal joints which can result in reducing deflections due to heavy loading. As shown in Table 9, keyways were significantly more effective in reducing deflection due to the heavier loads only in the a.m. hours and slightly less effective in the p.m. hours. The reduction in deflections at keyway joints was as high as 20 percent due to the heavy load of 900 KPa which corresponds to a 29,000 lbs axle.

## CONCLUSIONS

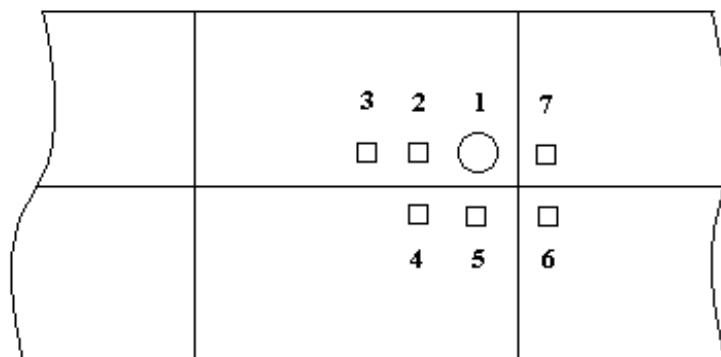

The main objective of this study was to evaluate the effectiveness of longitudinal joints in concrete pavements with and without keyways. All tests were performed on newly constructed pavement before opening to traffic. The State Materials Office will continue performing FWD testing and condition evaluation of the sections with and without keyways to determine the effect of traffic on the performance of joints. The following conclusions can be drawn based on the testing and analysis performed up to date:

- a. The statistical analysis performed indicated that keyway and non-keyway joints provided statistically similar load transfer efficiencies.
- b. Load transfer efficiency will vary in some cases due to temperature fluctuations. The curling of the slabs may have caused those variations.

- c. The efficiencies of load transfer at mid slabs are higher than the corners of the slabs. The lower load transfer at the corners may be due to the absence of tie bars in the immediate vicinity of transverse joints.
- d. Deflection measurements taken at early morning and mid afternoon differ significantly especially at the corner locations due to induced slabs curling.
- e. Using keyway joints resulted in reducing the deflection measurements at the standard 565 KPa FWD load for mid slab test locations only. However, deflections at keyway as well as non-keyway joints were very low making such reduction insignificant.
- f. Keyway joints were more effective in reducing deflections of the heavy 900 KPa FWD load during the a.m. testing time and less effective during the p.m. testing time.
- g. Although keyway joints did not increase the load transfer efficiency of longitudinal joints, they resulted in reducing the deflection of concrete slabs. The continuous monitoring of the test sections with and without keyways will show if the reduction in deflection will result in extending the service life of the pavement.
