| 16. Abstract <br> The four-section head Flashing Yellow Arrow (FYA) provided an opportunity to advance the operation of the left turn mode at intersections. In phase III of the project, the UCF team further enhanced the decision support system (DSS) by developing an exclusive hardware platform. The hardware platform was developed for two main objectives: first, to provide a generic device compatible with the different controller types used by different jurisdictions within the FDOT Districts and, second, to automate selection of the FYA left-turn modes based on available gaps in the opposing traffic at intersections acquired in real time from existing sensors in the field. Phase III provided conclusive offline testing using a peer-to-peer logic environment as well as online and field testing of the DSS. Peer-to-peer-logic offers the advantage of acquiring and analyzing real-time traffic data coupled with video feed, with the benefit of a safe environment. The testing verified that the system was able to accurately acquire real-time traffic conditions and react by switching between red and FYA modes in a rational manner consistent with driver expectations and left-turning gap acceptance thresholds. It was also concluded that coordinated signals with very long cycle lengths, 3 minutes and longer, help in providing adequate gaps even in heavy traffic patterns since most of the vehicle arrivals are in platoons and at the beginning of the cycle. However, short cycle lengths eliminate sufficient gap times even with coordination. Two methods were used to calculate the minimum gap: discrete and average approach. Although the average method provides a more conservative approach, the discrete approach was more accurate. The developed platform is applicable at any four-section head configuration to alter the left turn restriction throughout the day to maximize safety and efficiency of the intersections. |  |  |

## ACKNOWLEDGEMENTS

The authors would like to express their sincere appreciation to the Florida Department of Transportation (FDOT) and acknowledge the cooperation and support of Mr. Jim Stroz (District 5 Traffic Operations Engineer) for serving as the Project Manager and providing guidance during the course of this research. The UCF research team would like also to express their deepest gratitude to all Seminole County Traffic Engineering Staff, especially Chad Dickson and Jared Zabele, for their tremendous help in providing the testing environment in the lab (Naztec Cabinet and Controller, four-section head) as well as in the field. The authors are also grateful to Orange County Traffic Engineering Staff, especially Roger Smith, for providing the Siemens Controller and field testing, Osceola County Traffic Engineering Kevin Krug for providing a traffic cabinet to UCF, and Volusia County Traffic Engineering Bobby Maddox and Karl Ewald for their help in providing the Econolite Controller and support during the field testing. The UCF research team would like to acknowledge the following personnel:

## EXECUTIVE SUMMARY

The four-section head flashing yellow arrow (FYA) provided an opportunity to advance the operation of the left turn mode at intersections. In Phase III of the project, the UCF team further enhanced the decision support system (DSS) by developing an exclusive hardware platform. The hardware platform was developed for two main objectives. The first objective was to provide a generic device that would be compatible with the different controller types used by different jurisdictions within the FDOT districts. The DSS model testing through the pilot study conducted in Phase II as a proof of concept revealed several technical hitches related to the type of traffic signal controller utilized, such as Siemens controllers in Orange County versus Naztec in Seminole County. The second objective was to automate selection of the FYA left-turn modes based on available gaps in the opposing traffic at intersections acquired in real time from existing sensors in the field. The board used in the lab testing environment in Phase II was a one-way communication device. The decision of the algorithm was only displayed in a text box on the screen. An input/output (I/O) device was needed to complete the process and relay the decision back to the controller. The hardware platform receives volume data as well as signal phasing and timing (SPaT) inputs for a given cycle and returns recommendations to the controller.

A general wiring scheme capable of communicating with all TS-2 hardware layouts and controller models was achieved. Furthermore, a custom communication software with the new I/O board was developed using C\# language. The software included various parameters required for a successful configuration of the hardware. The parameters included acquisition of signal timing, acquisition of mode, extracting arrival data from the input channels, and outputting data to the output channels. A user interface (UI) was also developed (1) to specify particular parameters pertinent to each intersection and also adjust parameters while the operation is in progress and (2) to visualize the input data and the output decision as they occur.

Offline testing was conducted using a peer-to-peer logic setup. Peer-to-peer logic offers the advantage of acquiring and analyzing real-time traffic data coupled with video feed with the benefit of a safe environment. Vehicle detection through loops or video detection is sensed in the field by the cabinet and the controller. Then, it is mapped in real-time mode from the intersection approach to the controller and cabinet in the lab. The algorithm analyzes the traffic data and makes a decision accordingly that is communicated back to the controller and generates a realtime log recording the events. Peer-to-peer logic was a crucial step to verify and validate the algorithm and the software prior to field testing.

Having proven the DSS in a virtual environment, the next step was to test it in the real world as part of the decision making at a traffic management center (TMC) with field intersections. The testing of the DSS and the hardware platform was conducted by connecting directly to various controller and cabinet types in an online mode while allowing for instant validation of the DSS. The DSS was tested at six different intersections located in Seminole, Orange, and Volusia counties. Field data were collected from the loop detectors in real-time mode on a second-bysecond basis while monitoring traffic in each lane and detecting the status of the opposing green phase. Based on the intersection conditions and the gap threshold pertinent to the study intersection, the DSS sends the decision back to the controller in the field to apply it to the foursection head FYA.

Several issues and challenges were experienced in the field in the wiring setup and connections with certain controllers and cabinet types, especially with Siemens controllers and TS2 Type 2 Hybrid cabinets. In general, Siemens controllers don't have an output logic. In other words, it doesn't allow mapping an input as an output function as in the other controllers. Therefore, to overcome this issue, a peer-to-peer function on the controller itself was used to activate special functions to act as I/O logic. Furthermore, in the Temple Type 2 Hybrid cabinets, the I/O connections are wired differently from Type 1 . The I/O connections are connected to the controller through pin connections ( $\mathrm{a}, \mathrm{b}$, and c ) and are broken out on the back panel and then connected to the load switches. However, they don't break out load switches; that's why a "Phase Check" function was used in lieu of the vehicle detector. Lastly, a relay was used to regulate the signal between the DSS I/O board and the controller.

Two approaches were tested to calculate the minimum gap: discrete and average approach. Overall, the DSS results using the discrete method, showed steady fluctuations between the red arrow and yellow arrow decisions throughout the testing periods, which is considered reasonable, especially for a driver's expectation. This also indicated that the thresholds were rational and practical. The decisions were also verified from the log file data, which showed the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. However, the average method showed very conservative decisions. The average method was mainly used to verify saturated conditions and heavy traffic patterns assuming that the minimum gap is achieved between every two arriving vehicles every cycle in order to switch to a flashing yellow arrow. Although the average method provides a more conservative approach than the discrete one, the discrete approach is more accurate than the average approach.

It was also concluded that coordinated signals with very long cycle lengths, such as 3 minutes and longer, help in providing sufficient gaps even in heavy traffic patterns and during the peak hours because most of the vehicle arrivals are in platoons, due to coordination and at the beginning of the cycle. Therefore, in order to test the sensitivity of the algorithm to changes in the cycle length and also the difference between long and short cycles at coordinated signals, the intersection cycle length was reduced for a period of approximately 30 min . Although coordination helps in providing a more steady traffic flow with uniform arrivals of vehicles and eliminating the random arrivals, the DSS results showed that reducing the cycle length affects the traffic flow during the reduced green phase and eliminates sufficient gap times even with coordination.

The DSS testing confirmed the applicability and validity of the developed algorithm as well as the aforementioned procedure, criteria, and logic. The algorithm developed in this project will allow traffic signal controllers to be designed so that the appropriate left turn restriction can alter throughout the day to maximize safety and efficiency of the intersections. The value of the DSS in making real-time traffic decisions is crucial to improving the performance of the left turn and is applicable at any four-section head configuration.

## I. INTRODUCTION

### 1.1 Overview

Driven by the Decision Support System (DSS) and the interactive model developed in Phases I \& II (BDK78 TWO 977-15, BDV24 TWO 977-10) for the selection of the flashing yellow arrow (FYA) left-turn phasing mode, changing based on current traffic conditions at intersections, the UCF research team is aiming at developing an exclusive hardware platform for the DSS for two main objectives. The first objective was to provide a generic device that would be compatible with the different controller types used by different jurisdictions within the FDOT districts. The DSS model testing, through the pilot study conducted in phase II as a proof of concept revealed several technical hitches related to the type of traffic signal controller utilized, such as Siemens controllers in Orange County versus Naztec in Seminole County. The second crucial objective was the automation of the decision process at the Traffic Management Center (TMC) as well as in the field. The board used in the field/lab testing environment in Phase II was a one-way communication device. The decision of the algorithm was only displayed in a text box on the screen. An input/output device is needed to complete the process and relay the decision back to the controller. The UCF research team developed a hardware platform, based on the DSS, which is connected to the controller in the field and automate the modification-selection process of the FYA mode on a cycle-by-cycle basis. The hardware platform receives volume data as well as signal phasing and timing (SPaT) inputs for a given cycle and returns recommendations back to the controller.

The proposed DSS is being developed with the goal of safely optimizing traffic operations. In the case of a red arrow signaled for a left turn, the opposing through traffic during the green phase is constantly analyzed in real time to determine whether it would be optimal to switch the red arrow to a flashing yellow arrow. The DSS would provide traffic engineers at the TMC with the tools to utilize the efficiency of the permissive left-turn phase at both peak and off-peak times and fine-tune time-of-day phasing to reduce the delay at approaches with low volumes. The result will be greater safety, higher throughput, and fewer delays at these intersections, producing greater convenience and efficiency for Florida drivers.

### 1.2 Objectives

The main project objectives are:
1- Select an appropriate I/O Data Logger Device
2- Develop a communication layer compatible with all FDOT controllers
3- Fine tune the DSS algorithm and criteria and its user interface
4- Offline testing and validation of the algorithm for safe operation
5- Online Field testing for different controller types

### 1.3 Summary of Phase III Project Tasks

Task 1: Hardware Procurement and Interface Design
Task 2: Software Development and Algorithm Fine Tuning
Task 3: Offline Testing
Task 4: Online Testing
Task 5: Draft and Final Report

## II. HARDWARE PROCUREMENT AND INTERFACE DESIGN

### 2.1 Selection and Procurement of Digital Input/output Board

### 2.1.1 Examination of Boards in the Market

The first task in the project was to examine and study the available data logger hardware devices on the market. The goal is to procure a hardware board that is two-way communication and capable of connecting to the traffic controller on one side and to a computer on the other. The board used in the field/lab testing environment in phase II was a one-way communication device. The decision of the algorithm was only displayed in a text box on the screen. An input/output device is needed to complete the process and relay the decision back to the controller. The board is normally driven by a software interface that connects it to, and allows to be controlled by, the computer. This software is typically provided by the manufacturer to help developers interact with the hardware and build useful functionality into the system.

The project requirements for the hardware board are essentially the following:
i. Digital I/O board, i.e. capable of handling both digital input and output channels
ii. Has sufficient input and output channels to address multiple lanes and instructions
iii. Simple software interface compatible with Microsoft Visual Studio
iv. Portable

### 2.1.2 National Instruments

Our initial research choice led to National Instruments (www.ni.com). This is a company specializing in electronic test and measurement equipment. After consulting with their engineers, the following board and accessories were tentatively selected as shown in Figures 2-1 to 2-3.

Figure 2-1: NI-9375, PN: 785192-01

Figure 2-2: cDAQ-9171, PN: 781425-01

Figure 2-3: 782698-01 NI PS-10 power supply 24 VDC, 5A, 100-120/200-240 VAC

This board has the capability of handling 16 input and 16 output channels. It is compact and light weight which makes it ideal for the project. Unfortunately, after conducting significant research and effort with the company, it was found that the software provided was not easy to use, extremely bulky to install, and incapable of meeting the minimum requirements for our project. We had to look for another device.

### 2.1.3 CONTEC

We continued researching companies specializing in tests and measurements. A number of them were considered and our final choice was Contec (www.contec.com). Their subsidiary company is in Melbourne, FL (www.dtx.com). The software interface is relatively easy to install and use. The board is capable of handling 16 digital input and 16 digital output channels and it met the project requirements as shown in Figures 2-4 to 2-6.

### 2.2 Wiring and Connection Testing

The UCF ITS laboratory is currently equipped with different traffic controllers and cabinets that were provided by Seminole and Orange County Traffic Engineering Staff to support the different controller types in the market such as Siemens and Naztec. Econolite controller will also be provided by Osceola County traffic engineering staff. Seminole County Traffic Engineering Staff were very helpful in setting up the testing environment as shown in Figure 2-7 and mapping the intersection loop detectors from the field to the cabinet in the lab through FDOT using a peer-topeer logic. A workstation was also setup to monitor vehicle detection in real-time mode by CCTV cameras through the Bosch Video Management Software (BVMS). The intersection vehicle detection system through the loop occupancy and the CCTV cameras are connected to the I/O board and the communication software to receive data signaling the traffic flow on a second by second basis. Figures 2-8 to 2-10 show the inside of a Naztec controller cabinet and the different panels and modules needed for the wiring process.

Figure 2-9: The inside of a Naztec controller cabinet showing various modules

Figure 2-10: Detector channel outputs and bus interface unit (BIU)

### 2.2.1 Wiring Method from I/O Board to Controller

Traffic data received from, and the decision support system (DSS) logic instructions sent back to the controller are communicated through wiring connections to dedicated channels. Each traffic lane will use a separate input channel while other controller and/or traffic states will use one or more input channels. The logic instructions sent back to the controller will use one or more output channels. Additional wiring methods are used between the board and the controller to convert signals to and from the controller in order to accommodate various controller protocols. This task involves testing the wires and connections needed for the Siemens controllers in Orange County, Naztec controllers in Seminole County and Econolite controllers in Osceola/Volusia Counties to ensure compatibility. It should be noted that TS-2 controller cabinets are the only type approved by Traffic Engineering Research Lab (TERL) that supports the flashing yellow arrow (FYA) operation. TS-1 controllers are not capable of operating flashing yellow arrow signals. The following wiring technique is performed in the UCF ITS lab between the digital I/O board and a Naztec controller cabinet type TS-2 as an example for one of the intersection approaches and will be the standard for all other TS-2 controllers.

The digital I/O board was connected to the controller in a 2-way communication pattern; input and output as shown in Figures 2-11 and 2-12 showing the digital I/O board and its power supply.

Figure 2-11: The digital I/O board and its wiring to the controller

Figure 2-12: A close-up of the digital I/O board and its power supply
The wiring input needed to the board consist of 5 wires:
i) The left lane detection (vehicle detection in the left lane)
ii) The opposing through traffic lane detection (3 in this setting),
iii) The opposing through green phase status (red or green)

The wires were connected to the I/O board channels using the pre-emption outputs from the cabinet as shown in Figure 2-13. The preemption outputs were remapped and converted into detector inputs to be able to detect the signal drop low which indicates vehicle presence in each lane. The controller's input and output functions are hardwired to the Bus Interface Unit (BIU) which are communicated through the Synchronize Data Link Communication (SDLC) module. The detectors of the opposing through phases 2 and 6 will be used to activate the red arrow indication of the left turn (default mode) while phases 10 and 14 detectors will be utilized to activate the flashing yellow arrow indication.

Figure 2-13: Wiring from five pre-emption outputs to I/O Board

During operation, the DSS algorithm is continuously receiving and analyzing traffic data from the field. Once the algorithm reaches a decision to safely switch from a red arrow to a flashing yellow arrow, the decision is communicated back to the traffic controller via the output protocol of the digital I/O board.

The output protocol needs two wires to send a signal back to the traffic controller that, when high, instructs it to switch to a flashing yellow arrow mode based on the DSS. The detector channel outputs were utilized and converted into detector inputs for this purpose as shown in Figure 2-14. The two wires are connected to the detector channel L15 and logic ground L27. The controller logic ground on L27 receives the signal from the I/O board and sends it to detector L15 to put in a call to activate phase 10 for a flashing yellow arrow mode and inhibits phase 2, which is protected-only mode.

It should be noted that, for safety purposes, at the beginning of each cycle, the default of the left turn mode will be a red arrow and, depending on the traffic conditions, the DSS will determine whether there are enough gaps to switch to a FYA mode or not.

The output from the digital I/O board to the controller is wired through a relay before being fed to the controller as shown in Figure 2-15. The relay is used as a test-bed integration to keep the power supply of the I/O board isolated from the cabinet power supply. The wiring setup also included the connection of actual red and yellow arrow LED light modules to indicate the status of the operation in real time as shown in Figures 2-16 and 2-17.

Figure 2-14: Connections to the detector channel (L15) and logic ground (L27)

### 2.3 General Wiring and Connection Interface

### 2.3.1 General Wiring

The general wiring and connections as well as the hardware described in the previous sections are selected and assembled in a manner that would facilitate the seamless communication with virtually any TS-2 traffic controller on the market which can accommodate different protocols \& signal conversion. At a minimum, the Advanced Traffic Controller (ATC) should support the following requirements to be able to establish the above connections:

- 16 phases
- 4 rings
- 32 channel detection
- Input/output Logic
- Peer to Peer Logic

### 2.3.2 Connection Interface

The 2-way information to and from the computer communicating with the traffic controller is routed through the digital I/O board and driven by a software interface. Figure 2-18 shows an initial software interface version that was used to operate and test the wiring and connections. The interface has the responsibility of acting as a translator between the algorithm running on the computer side and the traffic controller present in the field.

Figure 2-18: Software interface between the computer and the controller

### 2.3.3 Data Received and Analyzed in Real Time

The basic communications software that accompanied the I/O board was limited compared to what was required in this project. It essentially establishes connection with the board and receives the data through the input channels. However, the data is accessed manually. What was needed, however, was automatic real-time access to the channel data as it is received by the board so that the algorithm can analyze traffic information in real-time and make accurate decisions. No time lag or decision gaps are expected to occur during the operation of the algorithm or its decision based on the traffic status. That's why, a custom communication interface is needed on top of the basic software which has three main functions; control the hardware, display real-time status and execute the proposed FYA algorithm. In Task 2, the UCF research team will develop a specific code to retrieve instantaneous channel input data, synchronize opposing thru green phase, analyze traffic information, provide the algorithm decision, and generate a real-time log recording the events.

### 2.4 Task 1 Conclusion

What has been achieved is a general design capable of communicating with all TS-2 hardware layouts and controller models currently in operation. As mentioned earlier, Phase III aims at developing a common method to connect to any controller regardless of its make or model. The algorithm running on the computer side and the user do not need to know what hardware exists on the other side. This conversion is handled by the interface layer which is designed to seamlessly perform this operation.

## III. SOFTWARE DEVELOPMENT

The software development task is conducted with two main goals; developing the communication layer and the user interface. These two sub-tasks are described in the next sections. The software is being developed in the C\# language under the Microsoft Visual Studio environment. It employs custom methods and functions as well as general libraries provided by the hardware manufacturer. These software components have been streamlined in a manner to achieve the initial project requirements.

### 3.1 Development of the Communication Layer

### 3.1.1 Custom Communication Software

A custom communication software has been developed that is capable of communicating with the new I/O hardware board in a bi-directional manner. Bi-directional communication means that the software is capable of both receiving data from and sending instructions to the hardware. This is crucial in the decision making process as traffic related commands will eventually be initiated to the controller in real-time. The software has three main functions; control the hardware, display real-time status and execute the proposed FYA algorithm. The UCF research team developed a specific code to retrieve instantaneous channel input data, synchronize opposing thru green phase, analyze traffic information, provide the algorithm decision, and generate a real-time log recording the events.

The software is currently collecting traffic data at the rate of 20 readings per second for each channel. This rate is more than sufficient to guarantee complete data reception in real-time without the possibility of missing traffic activity. The communication layer reception has been tested offline then online using the traffic controller in the UCF lab. The controller is connected to live traffic but, for safety reasons, it is not sending instructions to the field. However, live algorithm decisions will be conducted in Task 4. Field cameras mounted at the analyzed intersections were also used to corroborate the accuracy of the data communication.

### 3.1.2 Parameter Setting for Hardware Configuration

The software sets the required parameters for hardware configuration. It sets the number of lanes monitored, the data acquisition rate, and the channel configuration for sending and receiving data. The software is flexible enough to modify these parameters for different intersection settings. This capability allows for the analysis of virtually any traffic configuration at different intersections.

### 3.2 Development of the User Interface

A user interface (UI) has been developed to operate the software and establish a layer of communication with the user. The role of the user interface is to take commands from, and display information back to, the user. Some of the user interface development challenges are intuitiveness and user-friendliness. These criteria have been essential during the UI development phase.

### 3.2.1 Intuitive User Interface

The user interface developed for this project allows for monitoring the traffic lanes under analysis in real-time conditions. The main user interface is shown in Figure 3-1.

Figure 3-1: Main user interface

The interface is intuitive and very simple to operate. To start or stop the traffic monitoring process, the user presses the Start or Stop buttons, respectively. When the process is started, the real-time traffic activity is presented in a tabular scrolling list form where each traffic variable of interest is displayed. A time stamp and a record number are attached to each traffic activity which makes examining historical data straightforward. It should be noted that the sequential time stamp inside the log file is the incremental time starting from zero when the monitoring starts. However, the name of the file itself is the date and time of the analysis. The scrolling list allows the user to scroll back to previous records even when the system is running. Figure 3-2
shows a real time traffic display during the testing process. The interface was designed to be as user friendly as possible.

Figure 3-2: Real-time traffic display

### 3.2.2 Specification of Initial Parameters

Specification of the initial parameters has been implemented with the goal of maximizing user awareness of the traffic activity. For example, the rate of information displayed is set at a reasonable value for a human to comprehend. This rate is slower than that of the data acquisition. The software also specifies the value for the number of cycles used for dynamic traffic analysis. The incoming traffic information is displayed on the screen in a tabulated fashion. The user has the ability to scroll back to historical data while the system is operating and acquiring data.

Traffic decisions that are made in real-time are displayed to the user clearly. The user can examine the decisions versus the corresponding historical data for further analysis.
While carrying out real-time data acquisition, the software outputs the time stamped traffic data continuously to a log file for later analysis as shown in Figure 3-3. Offline examination of the traffic events and the corresponding decisions will help better understand traffic patterns and improve the decision algorithm.

Figure 3-3: Log file during real-time data acquisition

### 3.2.3 Adaptation to Various Scenarios

The software allows for the adaptation of various scenarios and methods regarding various situations. For example, traffic data can be input in various logical formats based on the hardware. The software is flexible enough to allow for logical format variation in data logic signals. Currently, the software is configured to accommodate the following signal logic as shown in Table 3-1.

Table 3-1: Event signal logic

| Event | Signal Logic |
| :--- | :---: |
| Car present | $\underline{\text { low }}$ |
| No Car | $\underline{\text { high }}$ |
| Opposing Green | $\underline{\text { low }}$ |
| $\underline{\text { Opposing Red }}$ | $\underline{\text { high }}$ |

Also, different intersections have different lane configurations. The software has the capability to configure different lane numbers and assignments based on the scenario under analysis. Currently, the software is configured for the following channels:

1. Left Lane under study with FYA
2. Opposing thru Green Phase (red or green)
3. Three opposing thru lanes:
[a] Inside Lane
[b] Middle Lane
[c] Outside Lane
Traffic data can follow many trends and have special cases. The software employs multiple approaches and techniques to examine the data and make a dynamic decision that best represents the real-time traffic.

### 3.3 Task 2 Conclusions

This task was mainly related to software development using C\# language. The main goal of this task is to enable is the custom software to communicate with the new digital I/O board to allow the software to set various parameters required for a successful configuration of the hardware. The parameters included acquisition of signal timing, acquisition of mode, extracting arrival data from the input channels, and outputting data to the output channels.

A User Interface (UI) was also developed to specify particular parameters pertinent to each intersection and also adjust parameters while the operation is in progress, and to visualize the input data and the output decision as they occur.

## IV. OFFLINE TESTING

### 4.1 Overview

The main goal of this task is to be able to communicate with various traffic controller types in an offline mode while allowing for the algorithm verification and enhancement using real-time traffic data. Offline testing provides this goal while maintaining a safe testing environment. It assists in developing the methods and techniques needed to examine the data and make a dynamic decision accordingly that best represents the real-time traffic.

The testing was conducted at UCF lab where actual intersection field data was obtained through loop detector mapping to the controller in the lab in real-time mode. This process is called peer-to-peer logic where an actual traffic controller is needed along with a controller interface device (CID) such as the digital input/output board. This setup is used in offline testing methodologies where an executable code such as algorithms or even an entire controller strategy, usually written for a particular system, is tested within a field environment that can help prove a concept or test a software. The testing environment required the following different components as shown in Figure 4-1:

1- Traffic signal cabinet with different controller types (Siemens, Naztec, \& Econolite)
2- Four-Section signal display (Flashing Yellow Arrow Signal)
3- CCTV camera feeds connected to a computer to monitor intersection traffic flow
4- Digital input/output data logger device
5- Communications software
Seminole County Traffic Engineering Staff were very helpful in setting up the testing environment and mapping the intersection loop detectors from the field to the cabinet in the lab. The CCTV cameras were also setup to monitor both the study approach as well as the traffic signal indication. The intersection vehicle detection system through the loop occupancy and the CCTV cameras were connected to the digital I/O board and the communication software to receive data signaling the traffic flow on a second by second basis. The permissive green times and the opposing through traffic were determined on a cycle-by-cycle basis from the field by the data logger software. The logic was based on modeling the inter-arrival time of vehicles and calculating the minimum headway and gap time per lane for the opposing traffic from the loop detectors data for the first two cycles before recommending a decision for the left turn signal head, either flashing or not, for the next cycle. This iterative process is repeated constantly on a cycle-by-cycle basis.

### 4.2 Peer-to-Peer Logic for Data Communication

As mentioned earlier, Offline testing was conducted using a peer-to-peer logic setup as shown in Figure 4-2. It should be noted that all District 5 counties will eventually be connected to the Florida Department of Transportation's (FDOT) fiber optics network as part of the statewide effort of updating Florida's Statewide ITS Architecture (SITSA), which charts the current and future course of ITS deployment. SITSA provides an integrated framework to ensure that various transportation technologies can work together smoothly and effectively on Florida's highways. Currently, Seminole, Orange and Volusia Counties are connected to FDOT's network which facilitated the communication with the three (3) main traffic controller types in District 5; Siemens, Naztec and Econolite shown in Figure 4-1.

Vehicle detection through loops or video detection is sensed in the field by the cabinet and the controller. Then it is mapped in real-time mode from the intersection approach to the controller and cabinet in the lab through an FDOT switch located at the UCF lab which communicates between the 2 controllers. The digital I/O board retrieve instantaneous channel input data in each lane through the lab cabinet. The algorithm analyzes the traffic data and makes a decision accordingly that is communicated back to the controller, and generate a real-time log recording the events. Peer-to-peer-logic offers the benefit of acquiring and analyzing real-time traffic data coupled with video feed with the benefit of a safe environment. The decision to switch to a red or a flashing yellow arrow is demonstrated by an actual left-turn traffic light with 4 -signal configuration installed in the lab. This makes the analysis intuitive and more realistic. Peer-to-peer-logic is a necessary step to verify and validate the algorithm and the software prior to field testing.

Figure 4-2: Peer-to-peer logic setup

### 4.3 Algorithm Logic

The original algorithm of the previous phase of the project helped achieve the proof of concept. It analyzed traffic data but without the ability to send back a decision to the controller. The decision reached after every analysis was only displayed to the user for verification. In this current phase, however, fine tuning and improving the algorithm and its accuracy are a natural progression in the development cycle. The algorithm decision is now communicated back to the controller for left turn mode adjustment. The decisions and the corresponding traffic data are stored in log files for further analysis and improvement.

The idea was to devise a technique that would predict traffic behavior in the short term based on historical data of the past few minutes using a moving average window. The method examines the traffic for a user defined number of cycles to predict the behavior for the following cycle. A decision is then made and the analysis window is updated by dropping the older cycle in the window and adding the current one. The process is then repeated continuously.

The algorithm applies a two-cycle window of historical traffic data for analysis at every cycle. During analysis, the algorithm constantly searches for gaps across all lanes of the traffic flow in the prior two cycles. Any gap meeting or exceeding the minimum headway threshold, shown in Table 4-1, is taken into account as a valid gap and stored in an accumulator. The decision to switch to a flashing yellow arrow is made when the cumulative valid gap(s) in the analysis window meet or exceed 6 times the minimum threshold, which is an average of 3 times per analysis cycle. As a safety precaution, the default and fallback decision is a red arrow.

The decision is made based on a number of parameters. These parameters include the number of opposing through lanes, the number of crossing lanes, the minimum headway in seconds corresponding to the number of lanes to cross, and the number of cycles in the analysis window. Table 4-1 shows the minimum headway (gap) in seconds corresponding to the number of lanes to cross. The thresholds used for different crossing number of lanes were obtained from the database of 30,000 cycles collected from the field.

Table 4-1: FYA algorithm minimum headway criteria

| No. of Opposing <br> Lanes Crossed | Min acceptable <br> Gap Time | Comments |
| :---: | :---: | :---: |
| $\mathbf{1}$ Lane | 3.0 s. | 1 Thru lane |
| 2 Lanes | 3.5 s. | 2 Thru lanes or <br> 1 Thru + 1 RT |
| 3 Lanes | 4.0 s. | 3 Thru lanes or <br> 2 Thru + 1 RT |
| 4 Lanes | 4.5 s. | 4 Thru lanes or <br> 3 Thru + 1 RT |

### 4.3.1 Discrete and Average Logic

Two approaches were tested to calculate the minimum gap; discrete and average approach. The discrete approach determines the time interval between the successive arrivals of vehicles for each lane independently and computes the lowest headway for each lane by cycle on a second by second basis. The algorithm then picks the minimum headway and compares it to the minimum acceptable gap shown in Table 4-1 needed for a vehicle to safely cross the given number of lanes. If the minimum headway for the corresponding number of lanes is achieved and repeated 3 times per cycle, the decision is made to switch to a flashing yellow mode. Otherwise, a red arrow is decided upon. The 3 time threshold was determined based on the statistical analysis of the cycle by cycle data collected from the field.

The average approach determines the heaviest lane of flow during the analysis period which is 2 cycles. It then determines the minimum gap duration by dividing the headway by the flow in the heaviest lane.

> Gap per Lane = Headway / Flow (Eq. 1)

If the minimum headway for the corresponding number of lanes is achieved and repeated 6 times in the 2 -cycles, the decision is made to switch to a flashing yellow mode. Otherwise, a red arrow is decided upon.

### 4.4 Offline Testing

The algorithm has been tested on a number of intersections in different counties (Seminole, Orange and Volusia) with different controller types, lane configurations and during different times of day using the peer-to-peer logic setup. The traffic data was streaming in real-time for the through lanes, the opposing green, and the left lane. Vehicle detection was in real-time mode and monitored by CCTV cameras through the Bosch Video Management Software (BVMS). Simultaneous video feed facilitated the visualization of the acquired data. The decision output by the algorithm only affected the controller in our lab and was inhibited from affecting the actual traffic. The following intersection and data provides an example of the testing procedure and results of the algorithm decision. The intersection is located in Seminole County at SR 436 (Semoran Blvd) and CR 427 (Ronald Reagan Blvd).

### 4.4.1 SR 436 and CR 427

One of the intersections used in testing the algorithm was the intersection of SR 436 and CR 427. The mainline SR 436 is a 6 lane divided arterial and CR 427 is a 2 lane road as shown in Figure $4-3$. There is a gas station on one of the corners and a small office space on the other corner. There is a rail road crossing on the east side of the intersection. The traffic gets heavier in the afternoon as shown in Figure 4-4. Due to the trees location which blocked part of the intersection view, a dual view was needed as shown in Figure 4-4. The intersection was monitored in the afternoon between 3:00 and 6:00 pm on a Thursday. As can be seen, the intersection is considered busy especially during the peak period. The study approach was the westbound left turn lane and the opposing eastbound 3 thru lanes. The testing was conducted during peak and off-peak times and using both approaches (discrete and average) to assess the sensitivity of the algorithm to traffic conditions.

Figure 4-3: SR 436 and CR 427 Geometry

Figure 4-4: SR 436 at CR 427 CCTV Camera Feeds

### 4.4.2 Decision Assessment and Field Data Validation

Tables 4-2 and 4-3 display the DSS log file and outputs for the intersection of SR 436 and CR 427 on a second by second basis for part of a cycle. The study approach has 3 opposing lanes to be crossed which correspond to a minimum acceptable gap time of 4.0 seconds as defined in Table 4-1. However, this minimum gap needs to be repeated at least 6 times, as specified in the algorithm, before deciding on a Flashing Yellow Arrow mode. As mentioned previously, the algorithm receives data for the first 2 cycles to calculate the minimum acceptable gap. Then the decision is provided in the third cycle and each cycle afterwards. Table 4-2 shows a short gap of 1.7 seconds that did not meet the minimum threshold of 4.0 seconds for the analyzed approach and, therefore, was not taken into account. Table 4-3, on the other hand, shows a longer gap of 6.1 seconds that exceeded the minimum threshold of 4.0 seconds and was counted as a valid gap. It should be noted that the gap time accuracy is in fraction of a second. The cycle length was around 230 seconds. The algorithm decision was to switch to a FYA mode most of the time between 3 and 5:00 pm based on the discrete approach. The average approach was recommending a red arrow all the time except during the SunRail passing due to the big gap created between the train and the intersection approach. However, approaching 5 pm , the algorithm decision was fluctuating from red arrow to FYA mode based on the discrete approach.

Figure 4-5 shows a 4-minute gap profile between $5: 56 \mathrm{pm}$ and 6:00 pm and displays about 12 gaps. Only one gap exceeded the minimum threshold ( 6.1 sec ) which is highlighted in green in Figure 4-6. It should be noted that the gap is determined only when there are no vehicles in any lane ( Y -axis $=0$ veh). More detailed log file is provided in Appendix A.

### 4.4.3 Log File Review

The software has been designed with continuous improvement in mind. All traffic data from all sensors and the corresponding algorithm decision are stored in real-time in a log file timestamped with the date and time of the start of the operation. This not only allows for offline verification of the existing software based on the rules and parameters currently implemented, but also helps pinpoint areas of improvement in efficiency and time saving. Log files can virtually be any size in length and are a great tool that provides for a thorough analysis and verification.

The log file for the above intersection is included in Appendix A. The log file shows vehicle arrival in fraction of second in each lane and the 2 methodologies used to calculate the minimum gap and their decisions (discrete and average decision) along with the cycle length.

Table 4-2: Short gap that did not meet the minimum threshold

Figure 4-5: Four-minute gap profile for SR 436 and CR 427

Figure 4-6: One-minute gap profile for SR 436 and CR 427

### 4.5 Task 3 Conclusions

The algorithm is implemented with the goal of safely optimizing traffic operations. The Decision Support System was tested at different intersections located in Seminole, Orange and Volusia Counties. Field data was collected in real time mode using peer-to-peer logic in order to map the field controller to the lab controller. Video data was collected at the same time period as the algorithm was tested in order to validate the algorithm decisions. The DSS testing confirmed the applicability and validity of the developed algorithm as well as the aforementioned procedure, criteria and logic. It is concluded that the average methodology provided a more conservative approach than the discrete one. However, the discrete approach is more accurate than the average approach.

### 4.5.1 Iterative Development Process

The software development lifecycle in general, and algorithm development in particular, follow an iterative development process. It starts with intersection requirements, moves to analysis and design, implementation, testing, evaluation, then cycles back to requirements as shown in Figure 4-7. Algorithm development lends itself to the iterative nature of development because it is a heuristic process where there is no known direct path to optimality.

Figure 4-7: Iterative development process

## V. ONLINE AND FIELD TESTING

### 5.1 Overview

The final task of this project involves field testing of the algorithm and the overall hardware platform developed throughout the project. The main goal was to connect directly to various controller and cabinet types in an online mode in the field while allowing for instant validation of the DSS. The system acquires and analyzes real-time traffic data, and the decisions are sent back to the controller, and at the same time, output is sent to the user's screen and saved to log files. The controller then applies the recommended decision to the four-section head display, whether in a flashing yellow arrow mode or red arrow, based on specific gap criteria reflecting intersection conditions. This task was performed on six intersections within the different counties in District 5 with the help of their traffic engineering staff. However, it is worth noting that Chad Dickson from Seminole County provided substantial help for Orange and Volusia County staff in the field wiring process and overcoming connection challenges. Field testing was executed at two intersections with Siemens controllers in Orange County, two intersections operated by Naztec controllers in Seminole County, and two intersections operated by Econolite controllers in Volusia County. The intersection photos are included in Appendix B, and the team photos are included in Appendix C. It should be noted that the intersection left turn approach required an actual four-section signal configuration instead of the five-section head display. The testing environment required the following components:

1- Traffic signal cabinet (TS2) with different controller types (Siemens, Naztec, \& Econolite)
2- Four-Section signal display (flashing yellow arrow signal)
3- Vehicle detection
4- Digital input/output data logger device
5- Communications software

The following sections explain in greater detail the testing procedure and provide an illustrative representation of how the system was connected in the field and the results of the Decision Support System (DSS) at each location.

### 5.2 Testing Scope and Specifications

The first step in the testing procedure is to select an intersection with specific characteristics, including the number of approach lanes for the left and through movements, type of signal head display, type of vehicle detection, traffic signal cabinet type, and controller type. The number of approach lanes is an essential component in determining the minimum gap time needed for the left-turning vehicles to safely cross the opposing through lanes. Furthermore, a single left turn lane is required for the permissive mode operation. Dual left turn lanes operate in a protected
mode only. Also, a 4-section configuration with the flashing yellow arrow (FYA) is needed instead of the 5-section display. As mentioned earlier, traffic signal cabinets TS2 are approved by the Traffic Engineering Research Lab (TERL) for the operation of the flashing yellow arrow. However, there exist TS2 type 1, type 2 and hybrid cabinets in the field which are acceptable but each one requires a different wiring setup as will be explained later. Vehicle detection through loop detectors or video detection is another requirement to determine the number of vehicles and inter-arrival times at the intersection approaches. Lastly, the three main controller types utilized in Florida; Siemens, Naztec and Econolite are also essential for the testing environment. The next sections describe the methods, techniques, issues and challenges faced during the field testing at each intersection in the different Counties.

The DSS communication software receives real-time data from the loop detectors signaling the traffic flow during the green phase on a second by second basis. The algorithm applies a twocycle window of historical traffic data for analysis at every cycle. During analysis, the algorithm constantly searches for gaps across all lanes of the traffic flow in the prior two cycles. Any gap meeting or exceeding the minimum headway threshold which is defined at each intersection, is taken into account as a valid gap and stored in an accumulator. The decision to switch to a flashing yellow arrow is made when the cumulative valid gap(s) in the analysis window meet or exceed 6 times the minimum threshold, which is an average of 3 times per analysis cycle. As a safety precaution, the default and fallback decision is a red arrow. This iterative process is repeated constantly on a cycle by cycle basis and is defined as the "Discrete" method. An additional method was also used and defined as the "Average" method. The average method determines the heaviest lane of flow and determines the average gap duration by dividing the amount of green time in each cycle by the flow in the heaviest lane and compares it to the minimum gap time. This method is similar to the saturation headway and provides an average gap time assuming a uniform arrival of vehicles. It doesn't take into account the stochastic nature of vehicle arrival or the actual arrival rate. However, it provides a more conservative approach by ensuring that the minimum gap is achieved between every two arriving vehicles every cycle in order to switch to a flashing yellow arrow.

In order to examine the sensitivity of the FYA DSS algorithm to the changes in traffic conditions during off peak and peak hours, the testing period was chosen from 2:00 to 5:00 pm which starts after the end of the mid-day peak hour and continues until the evening peak hour. Table 5-1 summarizes the list of intersections selected for testing in each County according to the above criteria as well as the cabinet type, controller type, study approaches, number of opposing lanes to cross, minimum acceptable gap time and the date when the site was visited.

### 5.3 Seminole County

### 5.3.1 Intersections Wiring and Challenges

Seminole County Traffic Engineering Staff (Chad Dickson and Jared Zabele) were extremely helpful in setting up the testing environment and wiring the connections to the cabinet and controller. The DSS I/O board requires specific input data from the cabinet and controller before sending a decision back to the controller. Input data include vehicle detection from each of the thru lanes as well as the left turn lane and status of the opposing thru phase. These data are needed as an output from the cabinet and the controller.

Seminole County utilizes Naztec Controllers and TS2 Type 1 Cabinets from Trafficware as shown in Figure 5-1. In a TS2 Type 1 cabinet, the Naztec controller’s input and output (I/O) functions are hardwired to the Bus Interface Unit (BIU) and directly connected to the Load Switches (LS) which are communicated through the Synchronize Data Link Communication (SDLC) module. However, the back panel provides an additional I/O functions for testing purposes which were used to connect to the DSS I/O board. The preemption outputs shown in Figure 5-2 were remapped and converted into detector inputs to the DSS board to be able to detect the low signal which indicates vehicle presence in each lane and also to detect the status of the opposing thru phase.

On the other hand, the output protocol from the DSS needs special wiring to send a signal back to the traffic controller which instructs it to switch to a flashing yellow arrow mode based on the available gaps. The detector channel outputs were utilized and converted into detector inputs for this purpose as shown in Figure 5-3. Two (2) wires are connected to the detector channel L15 and logic ground L27. The controller logic ground on L27 receives the signal from the DSS board and sends it to detector L15 to put in a call to activate phase 10 for a flashing yellow arrow mode and inhibits phase 2 which is protected only mode.

It should be noted that, for safety purposes, at the beginning of each cycle the default of the left turn mode is a red arrow and depending on the traffic conditions, the DSS determines whether there are enough gaps to switch to a FYA mode or not. Therefore, the detectors of the opposing through phases 2 and 6 are used for the red arrow indication of the left turn (default mode) while phases 10 and 14 detectors are used to activate the flashing yellow arrow indication.

### 5.3.2 Intersections Testing and DSS Results

As mentioned earlier, the two intersections selected for testing in Seminole County were:
1- CR 427 (Ronald Reagan Blvd) at Longwood Hills Road
2- Howell Branch Road at Lake Howell Road.
1- CR427 and Longwood Hills Road Intersection
CR 427 (Ronald Reagan Blvd) is a four lane divided principle arterial in Seminole County running in the north-south direction with a posted speed limit of 45 mph . Longwood Hills Road is an east-west two lane two way collector with a posted speed limit of 30 mph . Residential land uses exist on the east side of the intersection while a power plant and a commercial building exist on the northwest and southwest quadrants respectively as shown in Figure 5-4. The intersection has an exclusive northbound (NB) and southbound (SB) left turn lanes. The NB and SB left turn lanes have a four-section head display which operate in a protected permissive mode throughout the day. However, the side streets on Longwood Hills Rd/Shomate Drive have split phase operation. The traffic gets heavier in the southbound direction during the PM peak hour.

The study approaches were the northbound left turn (NBL) and southbound opposing thru (SBT). The southbound has 2 through lanes with loop detectors and an exclusive right turn lane without a loop detector as shown in Figure 5-3. Therefore, the DSS was setup to receive data from 2 lanes while the minimum gap time was set to cross 3 lanes. The intersection was running in a free mode and not coordinated. The cycle length varied according to the demand but was fluctuating between 80 and 130 seconds during the testing period.

Figure 5-4: CR 427 and Longwood Hills Rd intersection

## Decision Results and Assessment

Table 5-2 provides a summary of the log file and the DSS decisions in each cycle during the testing period for the NBL at CR 427. The study approach has 3 opposing lanes to be crossed which correspond to a minimum threshold of 24 second before deciding on a Flashing Yellow Arrow mode based on the discrete method. The 2-hour testing period resulted in 75 cycles with a majority of red arrow decisions ( 47 cycles) which shows a heavy traffic pattern even before the peak hour which started around 4:00 pm. Approaching the peak hour around 4 pm , the algorithm decision was red arrow for 29 cycles except for 5 cycles. The results also show steady fluctuations between the red arrow and yellow arrow decisions which are considered reasonable especially for driver's expectation. This also indicates that the threshold is rational and practical. Figure 5-5 shows a graphical representation of the gaps and the threshold. As can be seen on Figure 5-5, the max total gaps achieved were almost 50 seconds and the minimum gap was 0 seconds. The decisions can also be verified from the rest of the data which shows the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. For example, at 4:06 pm, the decision was to inhibit FYA due to absence of gaps which can be verified by the 54 vehicles, in the heaviest lane, that arrived during 47 seconds of green phase. The average method calculates the saturation headway and proves that the approach was operating at capacity. As mentioned earlier, the average method is more conservative and is looking for the minimum gap to be achieved between every two arriving vehicles. It is important to note that the discrete method is more accurate and reflects actual traffic conditions on a second-by-second basis.

Table 5-2: DSS results by cycle for CR 427 NBL

| Cycle No | Time Stamp | Discrete Gap (sec) | Discrete <br> Decision | Average <br> Gap (sec) | Average Decision | No of Veh/Green |  | Green Phase (sec) | Cycle <br> Length (sec) |

Figure 5-5: DSS results by cycle for CR 427 NBL

## 2- Howell Branch and Lake Howell Road Intersection

At the vicinity of the intersection, Howell Branch is a four-lane divided arterial running eastwest with a posted speed limit of 45 mph , connecting Goldenrod Road and US 17-92. Lake Howell Road is a two-lane road running north-south, connecting between SR 436 in the north to the County Line in the south with posted speed limit of 35 mph . Commercial land uses exist on all quadrants of the intersection as shown in Figure 5-6. The intersection has exclusive eastbound (EB) and westbound (WB) left turn lanes. The EB and WB left turn lanes have a four-section head display, which operates in a protected permissive mode throughout the day. The side streets on Lake Howell Rd also have exclusive left turn lanes with four-section head display. The traffic gets heavier in the eastbound direction during the PM peak hour.

The study approaches were the westbound left turn lane (WBL) and eastbound through lane (EBT). The eastbound has two through lanes with loop detectors. Therefore, the DSS was set up to receive data from two lanes, and the minimum gap time was set to cross two lanes as well. The intersection was running in a coordinated mode. The cycle length was almost steady throughout the testing period and was around 170 seconds.

Figure 5-6: Howell Branch Road and Lake Howell Road intersection

## Decision Results and Assessment

Table 5-3 provides a summary of the log file and the DSS decisions in each cycle during the testing period for the WBL along Howell Branch Road. The study approach has 2 opposing lanes to be crossed which correspond to a minimum threshold of 21 second before deciding on a Flashing Yellow Arrow mode based on the discrete method. The 2.5 hours testing period resulted in 49 cycles with a majority of yellow arrow decisions (31 cycles) which shows a light to moderate traffic pattern from 3:00 to 4:30 pm before the peak hour which started after 4:30 pm. Approaching the peak hour around 4:40 pm, the algorithm decision was red arrow for 11 cycles except for 3 cycles. The results also show steady fluctuations between the red arrow and yellow arrow decisions which are considered reasonable and indicate that the threshold is rational and practical. Figure 5-6 shows a graphical representation of the gaps and the threshold. As can be seen on Figure 5-7, the max total gaps reached 112 seconds and the minimum gap was 0 seconds at $5: 15 \mathrm{pm}$. The decisions was also verified from the rest of the data which shows the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. For example, at 4:06 pm, the decision was to inhibit FYA due to absence of gaps which can be verified by the 88 vehicles, in the heaviest lane, that arrived during 88 seconds of green phase. The average method calculates the saturation headway and proves that the approach was operating at capacity.

Table 5-3: DSS results by cycle for Howell Branch Rd WBL

| Cycle No | Time Stamp | Discrete <br> Gap (sec) | Discrete Decision | Average Gap (sec) | Average Decision | No of Veh/Green |  | Green <br> Phase | Cycle <br> Length |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |  | Lane 1 | Lane 2 |  |  |

### 5.4 Volusia County

### 5.4.1 Intersections Wiring and Challenges

Volusia County Traffic Engineering Staff (Bobby Maddox and Karl Ewald) were very helpful in selecting the intersections and conducting the testing. It should be noted that Chad Dickson and Jared Zabele from Seminole County were also available for setting up the wiring and connections to the cabinet and controller. The same input and output data was needed.

Volusia County study intersections utilized Econolite Controllers ASC/3-2100 and TS2 Type 1 Cabinets from Econolite as shown in Figure 5-8. As mentioned earlier, the controller's input and output (I/O) functions in TS2 Type 1 cabinets are hardwired to the Bus Interface Unit (BIU) and directly connected to the Load Switches (LS) which are communicated through the Synchronize Data Link Communication (SDLC) module. However, the Econolite cabinet didn’t breakout the detectors or load switch drivers on a back panel such as Naztec Cabinets. Therefore, to overcome this issue, vehicle detection from the inductive loops for the left turn (Phase 1) and the opposing thru (Phase 2) as well as the green status of the opposing thru (Phase 2) were interfaced through spare (empty) Load Switch sockets (24v side) in the cabinet and remapped with the Controller's I/O logic processor as shown in Figure 5-9. It is worth mentioning that Econolite controllers were the easiest of all controllers to setup a logic statement. The control wire for the DSS to determine a protected or FYA operation was input through Ped call 1 on the back panel of the cabinet to allow or omit FYA overlap using I/O Logic statements within the controller as in Figure 5-10.

### 5.4.2 Intersections Testing and DSS Results

As mentioned earlier, the two intersections selected for testing in Volusia County were:
3- Saxon Blvd at Threadgill Place
4- Saxon Blvd at Park and Ride Pl

## 3- Saxon Blvd and Threadgill Place Intersection

Saxon Blvd is a six-lane divided principle arterial in Volusia County running in the east-west direction with a posted speed limit of 45 mph . Threadgill Place is a minor local road running in the northbound direction. The area is predominantly commercial land uses and offices such as Lowe's, Five Guys and Jena Medical and Daytona Heart group as shown in Figure 5-11. The intersection has an exclusive eastbound (EB) and westbound (WB) left turn lanes. The EB and WB left turn lanes have a four-section head display which operate in a protected permissive mode throughout the day. The side street also on Threadgill Place has exclusive left turn lanes but with three section head display which operates in a permissive mode. It was expected that the traffic gets heavier in the westbound direction during the PM peak hour for drivers coming off of I-4. However, the traffic pattern stayed light to moderate throughout the testing period 3-5 pm.

The study approaches were the eastbound left turn (EBL) and westbound opposing thru (WBT). The westbound has 3 through lanes with loop detectors. Therefore, the DSS was setup to receive data from 3 lanes and the minimum gap time was set to cross 3 lanes as well. The intersection was running in a free mode and was not coordinated. The cycle length was fluctuating based on the demand throughout the testing period.

Figure 5-11: Saxon Blvd and Threadgill Place intersection

## Decision Results and Assessment

Table 5-4 provides a summary of the DSS decisions in each cycle during the testing period for the EBL along Saxon Blvd. The study approach has 3 opposing lanes to be crossed which correspond to a minimum threshold of 24 seconds before deciding on a Flashing Yellow Arrow mode based on the discrete method. The testing period lasted for 1.5 hours only due to the time taken for the wiring setup and connections. A total of 60 cycles with a majority of yellow arrow decisions ( 49 cycles) were observed which show a very light traffic pattern even during the peak hour until 5 pm . What was more interesting is the average method decisions which included a lot of yellow arrows. As mentioned before, the average method is a very conservative approach which requires that the minimum gap be available between every arriving vehicle. It assumes a uniform distribution of the vehicle's arrival without taking into account actual arrival patterns. Results also show steady fluctuations between the red arrow and yellow arrow decisions which are considered reasonable and indicate that the threshold is rational and practical. Figure 5-12 shows a graphical representation of the gaps and the threshold. As can be seen on Figure 5-12, the max total gaps reached 145 seconds and the minimum gap was 0 seconds at $4: 30 \mathrm{pm}$. The decisions was also verified from the rest of the data which shows the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. For example, at $4: 30 \mathrm{pm}$, the decision was to inhibit FYA due to absence of gaps which can be verified by the 75 vehicles, in the heaviest lane, that arrived during 55 seconds of green phase.

Table 5-4: DSS results by cycle for Saxon Blvd EBL

| Cycle No | Time Stamp | Discrete <br> Gap (sec) | Discrete <br> Decision | Average Gap (sec) | Average Decision | No of Veh/Green |  |  | Green Phase | Cycle <br> Length |

Figure 5-12: DSS results by cycle for Saxon Blvd EBL

## 4- Saxon Blvd and Park and Ride Intersection

Saxon Blvd is a six lane divided principle arterial in Volusia County running in the east-west direction with a posted speed limit of 45 mph . Park and Ride is just west of I-4 interchange ramps. The Park and Ride lot offers a central location where commuters can park their cars and make the transfer to a carpool or transit. The Saxon Boulevard Park and Ride is serviced by Votran via the SunRail Connector service. This location was selected due to its close proximity to I-4 interchange ramps and the fact that the previous intersection along Saxon Blvd didn't experience any congestion even during the peak hour. The main purpose was to test the DSS algorithm on a heavily congested six lane roadway and to capture any traffic heading towards I-4 during the peak hour. The area is predominantly service land uses such as Deltona Memorial Funeral Home, Race Track gas station and Park and Ride as shown in Figure 5-13. The intersection has an exclusive eastbound (EB) and westbound (WB) left turn lanes. The EB and WB left turn lanes have a four-section head display which operate in a protected permissive mode throughout the day. The side street also on Park and Ride has exclusive left turn lanes but with three section head display which operates in a permissive mode.

The study approaches were the westbound left turn (WBL) and eastbound opposing thru (EBT). The eastbound direction has 3 through lanes with loop detectors. Therefore, the DSS was setup to receive data from 3 lanes and the minimum gap time was set to cross 3 lanes as well. The intersection was running in a coordinated mode which was recently modified from running in a free mode. The cycle length was 150 seconds.

Figure 5-13: Saxon Blvd and Park and Ride intersection

## Decision Results and Assessment

Table 5-5 provides a summary of the DSS decisions in each cycle during the testing period for the WBL along Saxon Blvd. The study approach has three opposing lanes to be crossed, which corresponds to a minimum threshold of 24 seconds before deciding on a flashing yellow arrow mode based on the discrete method. The testing period lasted for 1.5 hours only due to the time taken for the wiring setup and connections, especially to map the loop detectors. A total of 42 cycles display a majority of yellow arrow decisions (26 cycles), suggesting a light to moderate traffic pattern, even during the peak hour. The average method also included several yellow arrow decisions. It was expected that the traffic would get heavier in the eastbound direction during the PM peak hour for drivers heading towards I-4. However, the traffic pattern stayed light to moderate throughout the testing period. In order to test the sensitivity of the algorithm to changes in the cycle length and also the difference between coordinated and uncoordinated signals, the intersection cycle length was reduced for a period of approximately 30 min between 3:40 and 4:10 pm as shown on Table 5-5. Although coordination helps in providing a more steady traffic flow with uniform arrivals of vehicles and eliminating the random arrivals, the DSS results showed that reducing the cycle length affects the traffic flow during the reduced green time and eliminates sufficient gap times even with coordination.

Table 5-5: DSS results by cycle for Saxon Blvd WBL

On the other hand, providing very long cycle lengths due to coordination increases available gaps in the traffic stream. The results also showed steady fluctuations between the red arrow and yellow arrow decisions which are considered reasonable and indicates that the threshold is rational and practical. Figure 5-14 shows a graphical representation of the gaps and the threshold. As can be seen on Figure 5-14, the max total gaps reached 147 seconds with the 150 coordinated cycle length. However, after reducing the cycle length, the minimum gap reached 0 seconds continuously for almost 9 cycles. The decisions was also verified from the rest of the data which shows the number of vehicles that arrived during the green phase along with the amount of green
time in each cycle and the cycle length. For example, at $3: 59 \mathrm{pm}$, the decision was to inhibit FYA due to absence of gaps which can be verified by the 47 vehicles, in the heaviest lane, that arrived during 46 seconds of green phase.

### 5.5 Orange County

### 5.5.1 Intersections Wiring and Challenges

Orange County Traffic Engineering Staff (Roger Smith and Michael Colon Rodriguez) were very helpful in selecting the intersections, setting up the connections and conducting the testing. It should be noted that Chad Dickson and Jared Zabele from Seminole County were also available for setting up the wiring and connections to the cabinet and controller. The same input and output data from the controller and cabinet was needed for the DSS. Orange County study intersections utilized Siemens Controllers M60 which is the latest version from Siemens to accommodate FYA and peer to peer logic. However, the two intersections selected for testing had different cabinet types. The intersection at John Young Parkway had a Naztec cabinet TS2 Type 1 as shown previously in Figure 5-1. The intersection at Orange Avenue had a TS2 Type 2 Hybrid Temple Cabinet as shown in Figure 5-15. Both locations experienced several challenges in the wiring setup. First, Siemens controllers don't have an output logic. In other words, it doesn't allow mapping an input as an output function such as in the other controllers. Therefore, to overcome this issue, we used peer-to-peer functions on the controller itself to activate special functions to act as I/O logic. Second, in the Temple Type 2 Hybrid cabinets, the I/O connections are wired differently from Type 1 . They are connected to the controller through pin connections ( $\mathrm{a}, \mathrm{b} \& \mathrm{c}$ ). Then they are broken out on the back panel and then connected to the load switches. However, they don't break out call switches that's why we had to use "Phase Check" function in lieu of vehicle detector. Third, a relay was used to regulate the signal between the DSS I/O board and the controller. The following is a summary of the connections at each location.

- John Young Pkwy @ SR408 EB Ramps: The Cabinet was Trafficware (Naztec) TS2 Type 1 but the intersection operating with Siemens M60 controller. Phases $1 \& 6$ utilize video detection while Phase 2 had inductive loop detectors. Vehicle detection was interfaced through loop panel output terminals. A relay was used for Phase 1 (FYA Phase) due to issues with Video detection holding a call while the interface unit was installed as shown in Figure 5-16. Using the controller's Peer to Peer functions to act as I/O logic, green status of opposing thru (phase 2) was mapped to Special function 2. The control wire to determine protected or FYA operation was input through Loop Panel detector 16 and remapped within controller Peer to Peer to call Special Function 1.
- Orange Ave @ Office Court: The Cabinet was Temple brand TS2 type 2 hybrid. Intersection operating with Siemens M60 controller. Vehicle detection was through inductive loops for all directions which was interfaced through back panel "Phase Check" terminal for Phase 1 for the left turn demand (FYA Phase) and Special Functions 2 \& 3 were remapped within controller's Peer to Peer I/O Logic for Phase 2 (opposing thru) as shown in Figure 517. Green status of opposing thru (Phase 2) is interfaced directly on back panel phase 2 green terminal. The control wire to determine protected or FYA operation was input through a relay into Ped call 1 and remapped within controller Peer to Peer to call Special Function 1 as shown in Figure 5-18.

### 5.5.2 Intersections Testing and DSS Results

As mentioned earlier, the two intersections selected for testing in Orange County were:
5- John Young Parkway at SR 408 EB Ramps
6- Orange Avenue at Office Court

## 5- John Young Parkway and SR 408 EB Ramps Intersection

John Young Parkway (JYP) is a north-south six lane divided principle arterial in Orange County with a posted speed limit of 45 mph . Within the vicinity of the intersection and between the SR 408 ramps, JYP has 8 lanes. The additional lane is used as an auxiliary lane for the westbound on ramp. SR 408 is an east-west expressway with 8 lanes and posted speed limit of 60 mph . JYP intersects with the eastbound off ramp and on ramp which is considered as T intersection. The area is predominantly residential on the west side and commercial land uses are on the east side as shown in Figure 5-19. The intersection has an exclusive southbound (SB) left turn lane. The EB approach has dual left turn lanes and single right turn lane. The SB left turn lane has a foursection head display which operates in a protected permissive mode throughout the day. This was considered a key location to test the DSS while crossing 4 lanes of traffic. The testing period lasted for 2 hours from 3:00 to 5:00 pm. It should be noted that due to the wiring issues and challenges mentioned above, we had to visit the site couple of times.

The study approaches were the southbound left turn (SBL) and northbound opposing thru (NBT). The northbound has 4 through lanes with loop detectors. Therefore, the DSS was setup to receive data from 4 lanes and the minimum gap time was set to cross 4 lanes as well. The intersection was running in a coordinated mode with Cycle length of 180 seconds.

Figure 5-19: JYP and SR 408 EB ramps intersection

## Decision Results and Assessment

Table 5-6 provides a summary of the DSS decisions in each cycle during the testing period for the SBL along JYP. The study approach has 4 opposing lanes to be crossed which corresponds to a minimum threshold of 27 seconds before deciding on a Flashing Yellow Arrow mode based on the discrete method. The testing period lasted for 2 hours only due to the time taken for the wiring setup and connections especially to use the relays and special functions. A total of 38 cycles with a majority of yellow arrow decisions ( 28 cycles) was observed, although there was heavy traffic pattern especially during the peak hour. The traffic pattern stayed moderate to heavy throughout the testing period. However, as mentioned earlier, coordinated signals with very long cycle lengths such as the 3 minute cycle help in providing sufficient gaps especially when most of the vehicle arrivals are in platoons due to coordination. The average method showed only one yellow arrow decision which shows that there was heavy traffic patterns.

On the other hand, the results showed steady fluctuations between the red arrow and yellow arrow decisions which are considered reasonable and indicates that the threshold is rational and practical. Figure 5-20 shows a graphical representation of the gaps and the threshold. As can be seen on Figure 5-20, the max total gaps reached 125 seconds and the minimum gap was 0 seconds at $4: 25 \mathrm{pm}$. The decisions was also verified from the rest of the data which shows the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. For example, at $4: 25$ pm, the decision was to inhibit FYA due to absence of gaps which can be verified by the 108 vehicles, in the heaviest lane, that arrived during 108 seconds of green phase. Excerpts from the log file for the above intersection is included in Appendix D.

Figure 5-20: DSS results by cycle for JYP SBL

## 6- Orange Avenue and Office Court Intersection

Orange Avenue is a five lane major arterial in Orange County running in the north-south direction with a posted speed limit of 45 mph . Office Court is a local road for the offices surrounding the site. The area is predominantly offices on the west side and there is a US post office on the east side as shown in Figure 5-21. This is a T intersection with an exclusive northbound (NB) left turn lane. The EB approach has single lane. The NB left turn lane has a four-section head display which operates in a protected permissive mode throughout the day. The testing period lasted for 2 hours from 3:00 to 5:00 pm.

The study approaches were the northbound left turn (NBL) and southbound opposing thru (SBT). The southbound has 2 through lanes with loop detectors. Therefore, the DSS was setup to receive data from 2 lanes and the minimum gap time was set to cross 2 lanes as well. The intersection was running in a coordinated mode with Cycle length of 150 seconds and sometimes reaching 300 seconds when there was no calls from the side street.

Figure 5-21: Orange Ave and Office Court intersection

## Decision Results and Assessment

Table 5-7 provides a summary of the DSS decisions in each cycle during the testing period for the NBL along Orange Avenue. The study approach has two opposing lanes to be crossed, which corresponds to a minimum threshold of 21 seconds before deciding on a flashing yellow arrow mode based on the discrete method. The testing period lasted for 2 hours due to the connection wiring to use the relays and special functions as explained earlier. A total of 43 cycles display a majority of yellow arrow decisions ( 27 cycles), despite a heavy traffic pattern, especially during the peak hour, which could be inferred from the decreasing gap, as shown in Figure 5-22. The traffic pattern stayed moderate to heavy throughout the testing period. However, as mentioned earlier, coordinated signals with very long cycle lengths, such as the 5-minute cycle, help in providing sufficient gaps, especially when most of the vehicle arrivals are in platoons due to coordination. The average method showed only two yellow arrow decisions, which shows that there was a heavy traffic pattern. A majority of the congestion was due to shockwaves from the downstream signal at Sand Lake Road, which brought the intersection to a halt. On the other hand, the results showed steady fluctuations between the red arrow and yellow arrow decisions, which was considered reasonable and indicated that the threshold was rational and practical. Figure 5-22 shows a graphical representation of the gap and the threshold. As can be seen on Figure 5-22, the maximum total gap reached 165 seconds and the minimum gap reached 0 seconds three times (Fig. 4-22). Figure 5-22 also shows a decreasing trend in the gaps when approaching the peak hour. The decisions were also verified from the rest of the data, which showed the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. At $4: 48 \mathrm{pm}$, the decision was to inhibit FYA due
to absence of gaps, which was verified by the 116 vehicles, in the heaviest lane, that arrived during 149 seconds of green phase. Furthermore, the 0 gap was also due to the backups and queues from the downstream intersection which affected the traffic flow at the study intersection.

Figure 5-22: DSS results by cycle for Orange Ave NBL

## VI. CONCLUSIONS

The four section head flashing yellow arrow (FYA) provided an opportunity to advance the operation of the left turn mode at intersections. In phase 3 of the project, the UCF team further enhanced the decision support system (DSS) by developing an exclusive hardware platform. The hardware platform was developed for two main objectives. First, to provide a generic device that would be compatible with the different controller types used by different jurisdictions within the FDOT Districts. The second objective is to automate selection of the FYA left-turn modes based on available gaps in the opposing traffic at intersections acquired in real time from existing sensors in the field.

A general wiring scheme capable of communicating with all TS-2 hardware layouts and controller models was achieved. Furthermore, a custom communication software with the new I/O board was developed using C\# language. The software includes various parameters required for a successful configuration of the hardware. The parameters included acquisition of signal timing, acquisition of mode, extracting arrival data from the input channels, and outputting data to the output channels. A User Interface (UI) was also developed to specify particular parameters pertinent to each intersection and also adjust parameters while the operation is in progress, and to visualize the input data and the output decision as they occur.

Offline testing was conducted using a peer-to-peer logic setup. Peer-to-peer-logic offers the advantage of acquiring and analyzing real-time traffic data coupled with video feed with the benefit of a safe environment. Vehicle detection through loops or video detection is sensed in the field by the cabinet and the controller. Then it is mapped in real-time mode from the intersection approach to the controller and cabinet in the lab. The algorithm analyzes the traffic data and makes a decision accordingly that is communicated back to the controller, and generate a realtime log recording the events. Peer-to-peer-logic was a crucial step to verify and validate the algorithm and the software prior to field testing.

The final step of this research was to test the DSS and the hardware platform in the field by connecting directly to various controller and cabinet types in an online mode while allowing for instant validation of the DSS. The DSS was tested at 6 different intersections located in Seminole, Orange and Volusia Counties. Field data was collected from the loop detectors in real time mode on a second by second basis while monitoring traffic in each lane and detecting the status of the opposing green phase. Based on the intersection conditions and the gap threshold, the DSS sends the decision back to the controller in the field to apply it to the four section head FYA. Several issues and challenges were experienced in the field in the wiring setup and connections with certain controllers and cabinet types especially with Siemens controllers and TS2 Type 2 Hybrid cabinets. In general, Siemens controllers don't have an output logic. In other words, it doesn't allow mapping an input as an output function as in the other controllers. Therefore, to overcome this issue, a peer-to-peer function on the controller itself was used to activate special functions to act as I/O logic. Furthermore, in the Temple Type 2 Hybrid cabinets,
the I/O connections are wired differently from Type 1. They are connected to the controller through pin connections ( $\mathrm{a}, \mathrm{b} \& \mathrm{c}$ ). They are broken out on the back panel and then connected to the load switches. However, they don't break out load switches, that's why a "Phase Check" function was used in lieu of the vehicle detector. Lastly, a relay was used to regulate the signal between the DSS I/O board and the controller.

Overall, the DSS results through the discrete method, showed steady fluctuations between the red arrow and yellow arrow decisions throughout the testing periods which are considered reasonable especially for driver's expectation. This also indicated that the thresholds were rational and practical. The decisions were also verified from the log file data which showed the number of vehicles that arrived during the green phase along with the amount of green time in each cycle and the cycle length. However, the average method showed very conservative decisions. The average method was mainly used to verify saturated conditions and heavy traffic patterns assuming that the minimum gap is achieved between every two arriving vehicles every cycle in order to switch to a flashing yellow arrow. Although the average method provides a more conservative approach than the discrete one, the discrete approach is more accurate than the average approach.

It was also concluded that coordinated signals with very long cycle lengths such as 3 minutes and longer help in providing sufficient gaps even in heavy traffic patterns and during the peak hours since most of the vehicle arrivals are in platoons due to coordination and at the beginning of the cycle. Therefore, in order to test the sensitivity of the algorithm to changes in the cycle length and also the difference between long and short cycles at coordinated signals, the intersection cycle length was reduced for a period of approximately 30 min . Although coordination helps in providing a more steady traffic flow with uniform arrivals of vehicles and eliminating the random arrivals, the DSS results showed that reducing the cycle length affects the traffic flow during the reduced green phase and eliminates sufficient gap times even with coordination.

The DSS testing confirmed the applicability and validity of the developed algorithm as well as the aforementioned procedure, criteria and logic. The algorithm developed in this project will allow traffic signal controllers to be designed so that the appropriate left turn restriction can alter throughout the day to maximize safety and efficiency of the intersections. The value of the DSS in making real-time traffic decisions is crucial to improving the performance of the left turn and is applicable at any four section head configuration.
